Abstract

A number of static and multi-resolution methods have been introduced in recent years to compress 3D meshes. In most of these methods, the connectivity information is encoded without loss of information, but user-controllable loss of information is tolerated while compressing the geometry and property data. All these methods are very efficient at compressing the connectivity information, in some cases to a fraction of a bit per vertex, but the geometry and property data typically occupies much more room in the compressed bitstream than the compressed connectivity data. In this paper, we investigate the use of polynomial linear filtering as studied in the Refs. [Taubin G. A signal processing approach to fair surface design. *Computer Graphics Proc.*, Annual Conference Series 1995;351–358; Taubin G, Zhang T, Golub G. Optimal surface smoothing as filter design. IBM Research report RC–20,404, 1996], as a global predictor for the geometry data of a 3D mesh in multi-resolution 3D geometry compression schemes. Rather than introducing a new method to encode the multi-resolution connectivity information, we choose one of the efficient existing schemes depending on the structure of the multi-resolution data. After encoding the geometry of the lowest level of detail with an existing scheme, the geometry of each subsequent level of detail is predicted by applying a polynomial filter to the geometry of its predecessor lifted to the connectivity of the current level. The polynomial filter is designed to minimize the l^2 -norm of the approximation error but other norms can be used as well. Three properties of the filtered mesh are studied next: accuracy, robustness and compression ratio. The Zeroth Order Filter (unit polynomial) is found to have the best compression ratio. But higher order filters achieve better accuracy and robustness properties at the price of a slight decrease of the compression ratio. © 2000 Elsevier Science Ltd. All rights reserved.

1. Introduction

Polygonal models are the primary 3D representations for the manufacturing, architectural, and entertainment industries. They are also central to multimedia standards such as VRML and MPEG-4. In these standards, a polygonal model is defined by the position of its vertices (geometry); by the association between each face and its sustaining vertices (connectivity); and optional colors, normals and texture coordinates (properties).

Several single-resolution [9,20] and multi-resolution methods [8,14,15,18] have been introduced in recent years to represent 3D meshes in compressed form for compact

storage and transmission over networks and other communication channels. In most of these methods, the connectivity information is encoded without loss of information, and user-controllable loss is tolerated while compressing the geometry and property data. In fact, some of these methods only addressed the encoding of the connectivity data [6]. Multi-resolution schemes reduce the burden of generating hierarchies of levels on the fly, which may be computationally expensive and time consuming. In some of the multi-resolution schemes the levels of detail are organized in the compressed data in progressive fashion, from low to high resolution. This is a desirable property for applications, which require transmission of large 3D data sets over low bandwidth communication channels. Progressive schemes are more complex and typically not as efficient as single-resolution methods, but reduce quite significantly the latency in the decoder process.

In this paper, we investigate the use of polynomial linear filtering [16,17], as a global predictor for the geometry data of a 3D mesh in multi-resolution 3D geometry compression schemes. As in other multi-resolution geometry compression schemes, the geometry of a certain level of detail is predicted as a function of the geometry of the next coarser level of detail. However, other 3D geometry compression schemes use simpler and more localized prediction schemes.

Although, we concentrate on the compression of geometry data, property data may be treated similarly. The methods introduced in this paper apply to the large family of multi-resolution connectivity encoding schemes. These linear filters are defined by the connectivity of each level of detail and a few parameters, which in this paper are obtained by minimizing a global criterion related to certain desirable properties. Our simulations present the least-square filters compared with some other standard filters.

In Ref. [12], the Butterfly subdivision scheme is used for the predictor. In Ref. [7], a special second-order local criterion is minimized to refine the coarser resolution mesh. The latter class of algorithms has concentrated on mesh simplification procedures and efficient connectivity encoding schemes. For instance, in the Progressive Forest Split scheme [18], the authors have used a technique where the sequence of splits is determined based on the local volume conservation criterion. Next, the connectivity can be efficiently compressed as presented in the aforementioned paper or as in Ref. [15].

Mesh simplification has also been studied in a different context. Several works address the remeshing problem, usually for editing purposes. For instance in Ref. [4], the harmonic mapping is used to resample the mesh. Thus, the remeshing is obtained by minimizing a global curvature-based energy criterion. A conformal map is used in Ref. [10] for similar purposes, whereas in Ref. [11] again a global length based energy criterion is used to remesh.

The organization of the paper is as following. In Section 2, we review the mesh topology based filtering and introduce the basic notions. In Section 3, we present two geometry-encoding algorithms. In Section 4, we analyze three desirable properties: accuracy, robustness and compression ratio. In Section 5, we present numerical and graphical results; and finally, the conclusions are contained in Section 6 and are followed by the bibliography.

2. Mesh topology based filtering

Consider a mesh $(\mathcal{V}, \mathcal{F})$ given by a list of vertex coordinates \mathcal{V} (the *mesh geometry*) of the nV vertices, and a list of polygonal faces \mathcal{F} (the *mesh connectivity*).

The mesh geometry can be thought of as a collection of three vectors (x,y,z) of length nV containing, respectively, the three coordinates of each vertex; alternatively we can see \mathcal{V} as representing a collection of nV vectors $(r_0, r_1, \dots, r_{nV})$ of length 3, each of them being the position vector of some mesh vertex. To the list \mathcal{F} we associate the symmetric $nV \times nV$ vertex to vertex incidence matrix M , and the $nV \times nV$ matrix K defined by:

$$K = I - DM \quad (1)$$

where D is the $nV \times nV$ diagonal matrix whose (i,i) element is the inverse of the number of first-order neighbors the vertex i has. As shown in Ref. [16], K has nV real eigenvalues all in the interval $[0,2]$.

Consider now a collection $P = (P_x(X), P_y(X), P_z(X))$ of three polynomials each of degree d , for some positive integer d .

Definition We call P a *polynomial filter of length $d + 1$ (and degree or order d)*, where its action on the mesh \mathcal{V}, \mathcal{F} is defined by a new mesh $\mathcal{V}^l, \mathcal{F}$ of identical connectivity but of geometry $\mathcal{V}^l = (x^l, y^l, z^l)$ given by:

$$x^l = P_x(K)x, \quad y^l = P_y(K)y, \quad z^l = P_z(K)z \quad (2)$$

A *rational filter (Q,P)* of orders (m,n) is defined by two collections of polynomials (Q_x, Q_y, Q_z) and (P_x, P_y, P_z) of degrees m , respectively, n , whose action on the mesh \mathcal{V}, \mathcal{F} is defined by the new mesh $\mathcal{V}^l, \mathcal{F}$ through:

$$\begin{aligned} Q_x(K)x^l &= P_x(K)x, & Q_y(K)y^l &= P_y(K)y, \\ Q_z(K)z^l &= P_z(K)z \end{aligned} \quad (3)$$

To avoid possible confusions, we assume $Q_x(K), Q_y(K)$ and $Q_z(K)$ invertible. We point out the filtered mesh has the same connectivity as the original mesh; only the geometry changes. Note also the filter works for non-manifold connectivity as well.

In this report we consider only polynomial filters, i.e. rational filters of the form $(1,P)$. In Ref. [3], the authors considered the case $(Q,1)$. Note the distinction between polynomial and rational filters is artificial. Indeed, any rational filter is equivalent to a polynomial filter of length nV , in general, and in fact, any polynomial filter of degree larger than nV is equivalent to a polynomial filter of degree at most $nV - 1$. These facts are results of the Cayley–Hamilton theorem (see Ref. [5], for instance) that says the characteristic polynomial of K vanishes when applied on K . Therefore:

$$Q(K)^{-1}P(K) = P_0(K) \quad (4)$$

for some polynomial P_0 of degree at most $nV - 1$. Hence, the notion of Infinite Impulse Response (IIR) filter does not

have any correspondence in the mesh topology based filtering, because any polynomial of higher order or rational filter is equivalent to a polynomial filter of degree at most $nV - 1$, thus, a Finite Impulse Response (FIR) filter. However, the difference between polynomial and rational filters lays in their implementation. The polynomial filter is easily implemented by a forward iteration scheme. The rational filter can be implemented by a forward–backward iteration scheme:

$$w = P_x(K)x \quad Q_x(K)x' = w \quad (5)$$

involving the solution of a linear system of size nV . For small degrees m, n compared to nV (when the rational form has an advantage), the backward iteration turns into a sparse linear system, and thus efficient methods can be applied to implement it.

Two particular filtering schemes are of special importance to us and are studied next. The first scheme is called the *Zeroth Order Filter* and is simply defined by the constant polynomial 1:

$$P_Z(X) = (1, 1, 1) \quad (6)$$

Technically speaking, with the order definition given before, this is a zero order filter, but the most general form of zero order filters would be constant polynomials, not necessarily 1. However, throughout this paper we keep this convention to call the constant polynomial 1, the *Zeroth Order Filter*. Note its action is trivial: it does not change anything.

The second distinguished filtering scheme is called *Gaussian Smoothing* and it is a first-order filter defined by:

$$P_G(X) = (1 - X, 1 - X, 1 - X) \quad (7)$$

Using the definition of K and the filter action on the mesh geometry, the geometry of the Gaussian filtered mesh is given by:

$$x' = DMx, \quad y' = DMy, \quad z' = DMz \quad (8)$$

which turns into the following explicit form (using the position vectors r_i and the first-order neighborhood i^* of vertex i):

$$r'_i = \frac{1}{|i^*|} \sum_{v \in i^*} r_v \quad (9)$$

In other words, the new mesh geometry is obtained by taking the average of the first-order neighbors' positions on the original mesh.

3. The progressive approximation algorithms

In progressive transmission schemes, the original mesh is represented as a sequence of successively simplified meshes obtained by edge collapsing and vertex removal. Many simplification techniques have been proposed in the literature. For instance in Ref. [18] the progressive forest split method is used. It consists of partitioning the mesh into disjoint patches and in each patch a connected sequence of edge collapsing is performed.

The meshes we are using here have been simplified by a clustering procedure. First, all the coordinates are normalized so that the mesh is included in a 3D unit cube. Next the cube is divided along each coordinate axis into 2^B segments (B is the *quantizing rate*, representing the number of bits per vertex and coordinate needed to encode the geometry), thus obtaining 2^{3B} smaller cubes. In each smaller cube, all the edges are collapsed to one vertex placed in the center of the corresponding cube. The mesh thus obtained represents the quantized mesh at the finest resolution level. The coarsening process proceeds now as follows: 2^{3K} smaller cubes are replaced by one of edge size 2^K times bigger, and all the vertices inside are removed and replaced by one placed in the middle of the bigger cube. Next, the procedure is repeated until we obtain a sufficiently small number of vertices (i.e. a sufficient coarse resolution).

At each level of resolution, the *collapsing ratio* (i.e. the number of vertices of the finer resolution, divided by the number of vertices of the coarser resolution) is not bigger than 2^{3K} . In practice, however, this number could be much smaller than this bound, in which case some levels may be skipped. After l steps, the number of bits needed to encode one coordinate of any such vertex is $B - lK$. Thus, if we consider all the levels of detail and a constant collapsing ratio R , the total number of bits per coordinate needed to encode the geometry becomes:

$$M_b = NB + \frac{N}{R}(B - K) + \frac{N}{R^2}(B - 2K) + \dots + \frac{N}{R^L}(B - LK)$$

where N is the initial number of vertices and L the numbers of levels. Assuming $1/R^L \ll 1$ we obtain

$$M_b = NB \frac{R}{R - 1} + NK \frac{R}{(R - 1)^2}.$$

Thus, the number of bits per vertex (of initial mesh)

Table 1
The data packet structure for the basic encoding algorithm

$Mesh_{nL-1}$	$Map_{nL-2,nL-1}&Conn_{nL-2}$	$Param_{nL-2}$	$Diff_{nL-2}$...	$Map_{0,1}&Conn_0$	$Param_0$	$Diff_0$
---------------	-------------------------------	----------------	---------------	-----	--------------------	-----------	----------

and coordinate turns into:

$$N_{\text{bits}} \approx \frac{R}{R-1} \left(B + \frac{K}{R-1} \right) [\text{bits/vertex-coordinate}] \quad (10)$$

Thus, if we quantize the unit cube using $B = 10$ bits and we resample at each level with a coarsening factor of $2^K = 2$ and a collapsing ratio $R = 2$, we obtain the sequence as $B/K = 10$ levels of details encoded using an average of 22 bits/vertex-coordinate, or 66 bits/vertex (including all three coordinates). Thus, a single resolution encoding would require only B (10, in this example) bits per vertex and coordinate in an uncompressed encoding. Using the clustering decomposition algorithm, the encoding of all levels of details would require N_{bits} (given by Eq. (10)), about 22 in this example, which is more than twice the single resolution rate.

In this scenario, no information about the coarser resolution mesh has been used to encode the finer resolution mesh. In a progressive transmission, the coarser approximation may be used to predict the finer approximation mesh and thus only the differences should be encoded and transmitted. Moreover, the previous computations did not take into account the internal redundancy of the bit stream. An entropy encoder would perform much better than Eq. (10). In this paper, we do not discuss the connectivity encoding problem, since we are interested in the geometry encoding only. Yet, we assume at each level of detail the decoder knows the connectivity of that level mesh.

Suppose $(Mesh_{nL-1}, map_{nL-2,nL-1}, Mesh_{nL-2}, map_{nL-3,nL-2}, \dots, map_{1,2}, Mesh_1, map_{0,1}, Mesh_0)$ is the sequence of meshes obtained by coarsening algorithm, where $Mess_{nL-1}$ is the coarsest resolution mesh, $Mess_0$ the finest resolution mesh, and $map_{l-1,l} : \{0, 1, \dots, nV_{l-1} - 1\} \rightarrow \{0, 1, \dots, nV_l - 1\}$ is the *collapsing map* that associates to the nV_{l-1} vertices of the finer resolution mesh, the nV_l vertices of the coarser resolution mesh where they collapse. Each mesh $Mess_l$ has two components $(Geom_l, Conn_l)$, the geometry and connectivity, respectively, as explained earlier. We are concerned with the encoding of the sequence of geome-

tries $(Geom_{nL-1}, Geom_{nL-2}, \dots, Geom_1, Geom_0)$. Our basic encoding algorithm is the following.

3.1. The basic encoding algorithm

Step 1. Encode $Geom_{nL-1}$ using an entropy or arithmetic encoder;

Step 2. For $l = nL - 1$ down to 1 repeat:

Step 2.1 Based on mesh $Mess_l$ and connectivity $Conn_{l-1}$ find a set of parameters $Param_{l-1}$ and construct a predictor of the geometry $Geom_{l-1}$:

$G\hat{e}om_{l-1} = \text{Predictor}$

$(Mesh_l, Conn_{l-1}, map_{l-1,l}; Param_{l-1})$

Step 2.2 Encode the parameters $Param_{l-1}$;

Step 2.3 Compute the approximation error $Diff_{l-1} = Geom_{l-1} - G\hat{e}om_{l-1}$ and encode the differences. \diamond

The decoder will reconstruct the geometry at each level by simply adding up the difference to his prediction:

$$Geom_{l-1} = \text{Predictor}(Mesh_l, Conn_{l-1}, map_{l-1,l}; Param_{l-1}) + Diff_{l-1}$$

It is clear that different predictors yield different performance results. In the next section, we present several desirable properties of the encoding scheme.

The data packet structure is represented in Table 1.

The *Predictor* consists of applying the sequence of operators *extension*, where the geometry of level l is extended to level $l - 1$, and *update*, where the geometry is updated using a polynomial filter whose coefficients are called *parameters* of the predictor and whose matrix is the finer resolution incidence matrix K_{l-1} .

The extension step is straightforwardly realized using the collapsing maps:

$$r_i^{l-1;ext} = r_{map_{l-1,l}(i)}^l \quad (11)$$

Table 2

Thus the first “prediction” of the new vertex i is on the same point where it collapses, i.e. the position of the vertex $map_{l-1,l}(i)$ in mesh l . Next, the updating step is performed by polynomial filtering as in Eq. (2). The filter coefficients are the predictor parameters and have to be found and encoded. On each coordinate, we use a separate filter. In the next section, we introduce different criteria to measure the prediction error associated to a specific property. In Ref. [18], Taubin filters (i.e. of the form $P(X) = (1 - \lambda X)(1 + \mu X)$) have been used as predictors, but no optimization of the parameters has been done. Here, we use more general linear filters taking into account several performance criteria as well.

More specific, let us denote by $x_i^{l-1;ext}$ the nV_{l-1} -vector of x -coordinates obtained by extension (11), and by $x^{l-1;updt}$ the filtered vector with the polynomial $p_x(X) = \sum_{k=0}^d c_k X^k$

of degree d ,

$$x^{l-1;updt} = P_x(K_{l-1})x^{l-1;ext} \tag{12}$$

Let r^{l-1} denote the $nV_{l-1} \times 3$ matrix containing all the coordinates in the natural order, $r^{l-1} = [x^{l-1}|y^{l-1}|z^{l-1}]$, similar for $r^{l-1;updt}$. The update is our prediction for the geometry $Geom_{l-1}$. Then the coefficients are chosen to minimize some l^p -norm of the prediction error:

$$\min_{\text{Filters Coefficients}} J^{l-1} = \|r^{l-1} - r^{l-1;updt}\|_p \tag{13}$$

Note the optimization problem decouples into three independent optimization problems, because we allow different filters on each coordinate. The polynomial $P_x(X)$ can be represented either in the power basis, i.e. $P_x(X) = \sum_{k=0}^d c_k X^k$, or in another basis. We tried the Chebyshev basis as well, in which case $P_x(X) = \sum_{k=0}^d c_k T_k(X)$ with T_k

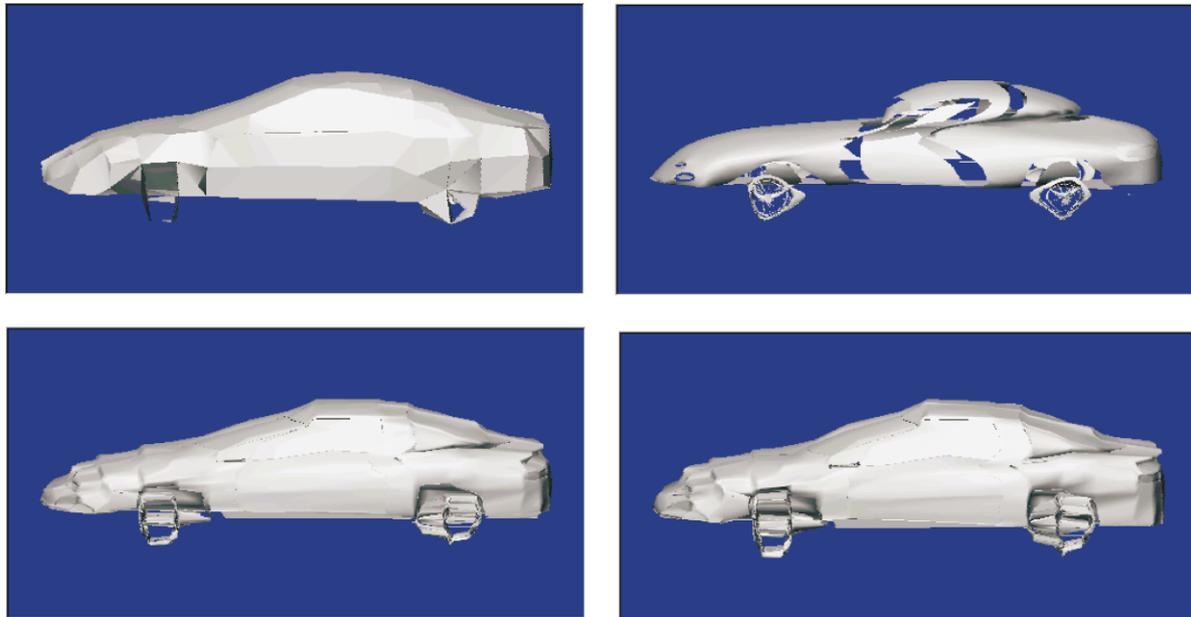

Fig. 2. The car mesh at the finest resolution level when no difference is used and the filtering is performed by: the Zeroth Order Filter (top left); the Gaussian Smoother (top right); the least-squares filter of order 1 (bottom left) and the least-squares filter of order 3 (bottom right).

Table 3

Filter's degree	1	2	3	4	5	6	7
bits/vertex	14.71	14.82	14.85	14.89	14.96	15.04	15.11

the k th Chebyshev polynomial. On each coordinate, the criterion J^{l-1} decouples as follows:

$$\begin{aligned}
 J^{l-1} &= \|(J_x^{l-1}, J_y^{l-1}, J_z^{l-1})\|_p, & J_x^{l-1} &= \|A_x c_x^{l-1} - x^{l-1}\|_p, \\
 J_y^{l-1} &= \|A_y c_y^{l-1} - y^{l-1}\|_p, & J_z^{l-1} &= \|A_z c_z^{l-1} - z^{l-1}\|_p,
 \end{aligned}
 \tag{14}$$

where the $nv \times d + 1$ matrix A_x is either

$$A_x = [x^{l-1;updt} | K_{l-1} x^{l-1;updt} | \dots | K_{l-1}^d x^{l-1;updt}] \tag{15}$$

in the power basis case, or

$$A_x = [x^{l-1;updt} | T_1(K_{l-1}) x^{l-1;updt} | \dots | T_d(K_{l-1}) x^{l-1;updt}] \tag{16}$$

in the Chebyshev basis case. c_x^{l-1} is the $d + 1$ -vector of the x -coordinate filter coefficients and x^{l-1} the nV_{l-1} -vector of the actual x -coordinates all computed at level $l - 1$. Similar for A_y, A_z, c_y, c_z , and y^{l-1}, z^{l-1} .

The basic encoding algorithm can be modified to a more general context. The user may select the levels for which the differences are sent. Then, for those levels the differences are not sent, the extension step to the next level has to use the predicted values instead of the actual values of the current level. In particular, we may want to send the differences starting with level $nL - 1$ and going down to some

level $S + 1$; then, from level S down to level 0, we do not send any difference but just the parameters, excepted for the level 0 when we send the differences as well. The algorithm just described is presented next.

3.2. The variable length encoding algorithm

Step 1. Encode $Mesh_{nL-1}$;

Step 2. For $l = nL - 1$ down to S repeat:

Step 2.1 Estimate the parameters $Param_{l-1}$ by minimizing J^{l-1} , where the predictor uses the true geometry of level l , $Geom_l$:

$$\begin{aligned}
 \hat{Geom}_{l-1} \\
 = f(Conn_l, Conn_{l-1}, map_{l-1,l}, Geom_l; Param_{l-1})
 \end{aligned}$$

Step 2.2 Encode the parameters $Param_{l-1}$;

Step 2.3 If $l \neq S$, encode the differences $Diff_{l-1} = Geom_{l-1} - \hat{Geom}_{l-1}$;

Step 3. For $l = S - 1$ down to 1

Step 3.1 Estimate the parameters $Param_{l-1}$ by minimizing J^{l-1} where the predictor uses the estimated geometry of level l :

$$\begin{aligned}
 \hat{Geom}_{l-1} \\
 = f(Conn_l, Conn_{l-1}, map_{l-1,l}, \hat{Geom}_l; Param_{l-1})
 \end{aligned}$$

Step 3.2 Encode the parameters $Param_{l-1}$;

Table 5
Compression ratios in the single resolution implementation of the variable length encoding algorithm applied to the car mesh rendered in Fig. 1

Filter	Zeroth Order	Gaussian Smoothing	LS of degree 1	LS of degree 3
Coarsest mesh	795	795	795	795
Coefficients	0	0	168	336
Differences	27,489	27,339	25,867	25,532
Total (bytes)	28,306	28,156	26,859	26,690
Rate (bits/vertex)	17.71	17.62	16.81	16.68
l^2 error/vertex(10^{-4})	11.96	18.64	9.33	8.44

Table 6
Compression ratio results for several filtering schemes applied to the round table mesh rendered in Fig. 5

Filter	Zeroth Order	Gaussian Smoothing	LS of degree 1	LS of degree 3
Coarsest mesh	438	438	438	438
Coefficients	0	0	168	336
Differences	22,739	51,575	23,645	23,497
Total (bytes)	23,196	52,032	24,274	24,295
Rate (bits/vertex)	15.63	35.07	16.36	16.37

Table 7
Compression ratios for different filter lengths, in power basis, for the round table

Filter's degree	1	2	3	4	5	6	7
bits/vertex	16.36	16.34	16.37	16.50	16.62	16.73	16.88

Step 4. Using the last prediction of level 0, encode the differences, $Diff_0 = Geom_0 - \hat{G}eom_0$. \diamond

In this case, the data packet structure is the one represented in Table 2. In particular, for $S = nL$ only the last set of differences is encoded. This represents an alternative to the single-resolution encoding scheme.

4. Desired properties

In this section, we discuss three properties we may want the encoding scheme to possess. The three properties: accuracy, robustness, and compression ratio yield different opti-

mization problems all of the type mentioned before. The l^p -norm to be minimized is different in each case. For accuracy the predictor has to minimize the l^∞ norm, for robustness the l^2 norm should be used, whereas the compression ratio is optimized for $p \in [1, 2]$ in general. Thus, a sensible criterion should be a trade-off between these various norms. Taking the computational complexity into account, we have chosen the l^2 -norm as our criterion and in the following section of examples, we show several results we have obtained.

4.1. Accuracy

Consider the following scenario: suppose we choose $S = nL$, the number of levels, in the variable length encoding algorithm. Suppose also the data block containing the level zero differences is lost (note this is the only data block containing differences because $S = nL$). In this case, we would like to predict the finest resolution mesh as accurately as possible based on the available information. Equivalently, we would like to minimize the distance between $Mesh_0$ and the prediction $\hat{M}esh_0$, under the previous

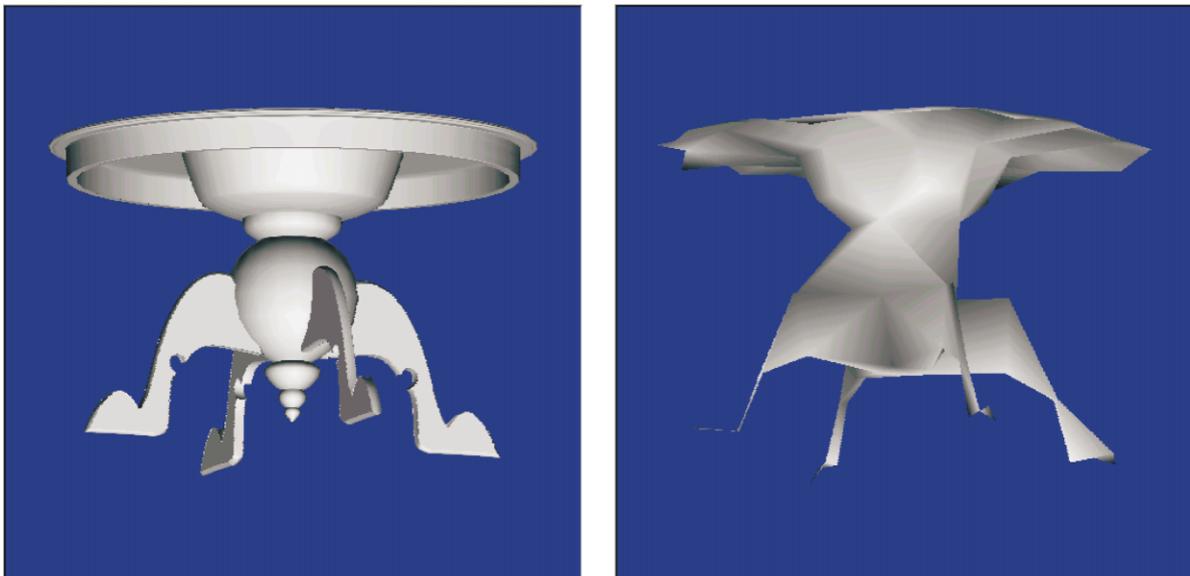

Fig. 5. The round table mesh at the finest resolution (left) and the coarsest resolution (right) after seven levels of reduction.

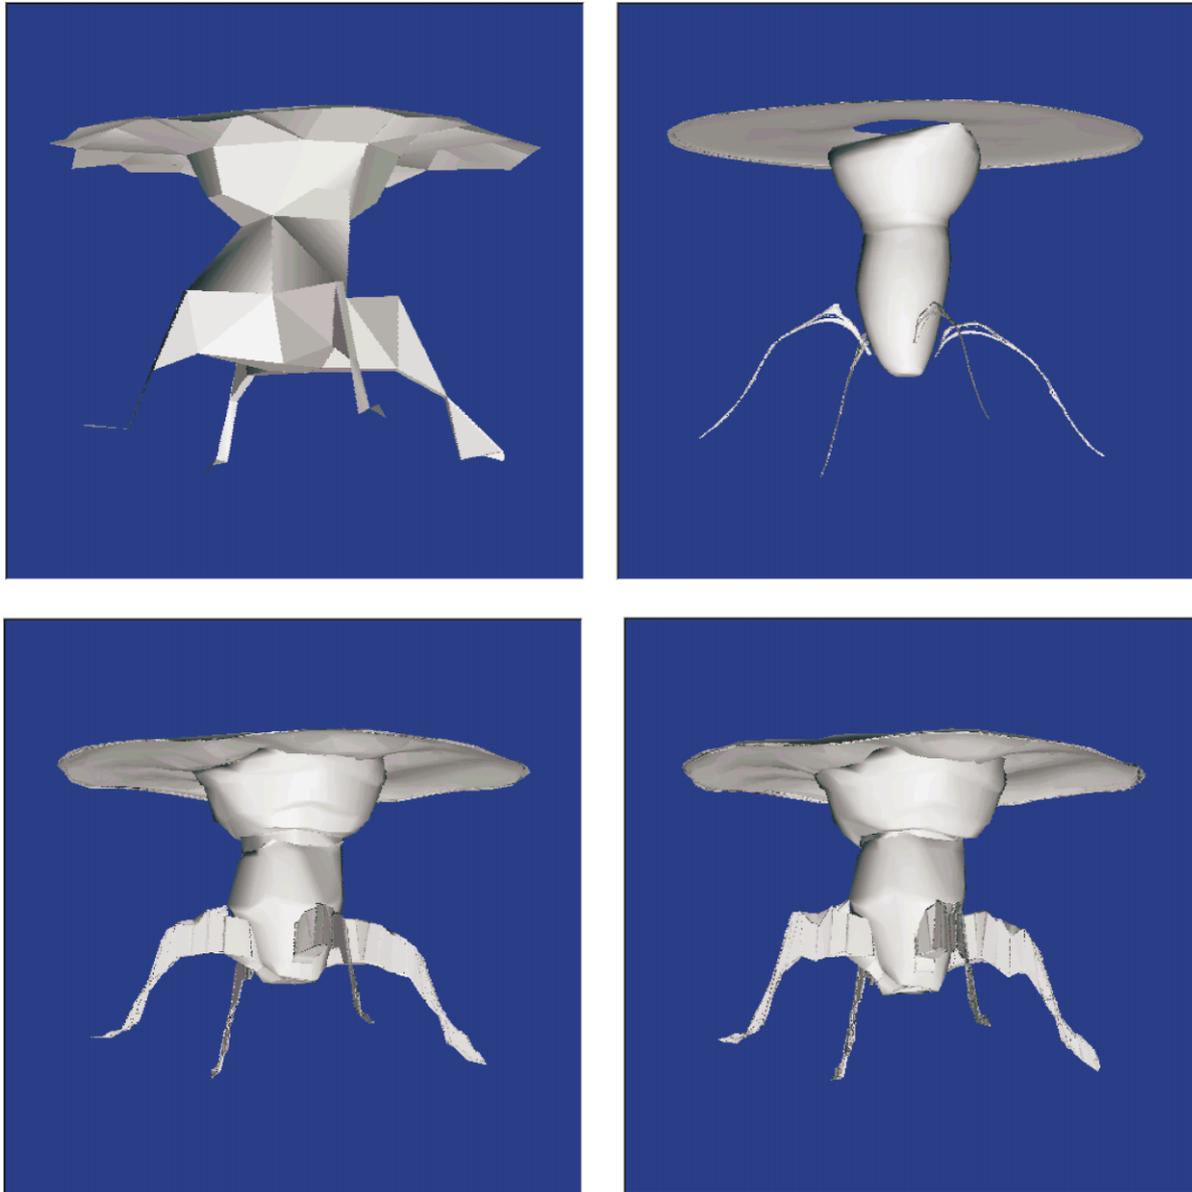

Fig. 6. The round table mesh at the finest resolution level when no difference is used and the filtering is performed by: the Zeroth Order Filter (top left); the Gaussian Smoother (top right); the least squares filter of order 1 (bottom left) and the least squares filter of order 3 (bottom right).

hypothesis. There are many ways of measuring mesh distances. One such measure is the Hausdorff distance. Although, it describes very well the closeness of two meshes, the Hausdorff distance yields a computational expensive optimization problem. Instead of Hausdorff distance one can consider the maximum distance between vertices (i.e. the l^∞ -norm, see Ref. [1]):

$$\varepsilon_a = \max_{0 \leq i \leq nV_0 - 1} \|r_i^0 - \hat{r}_i^0\| =: \|r^0 - \hat{r}^0\|_{l^\infty}$$

Note the l^∞ -norm is an upper bound for the Hausdorff distance. Consequently ε_a controls the meshes closeness as well. As mentioned in the previous section, the optimiza-

tion problem (13) decouples in three independent optimization problems. For $p = \infty$, these have the following form:

$$\inf_c \|Ac - b\|_{l^\infty} \tag{17}$$

where A was introduced by Eqs. (15) and (16), depending on the basis choice, c is the nf -vector of unknown filter coefficients, and b is one of the three vectors x , y or z . For $0 \leq i \leq nV - 1, 0 \leq j \leq fL - 1$, $A = [a_{ij}]$, $b = (b_i)$ and writing $c_j = f_j - g_j$ with $f_j \geq 0$, the positive part, and $g_j \geq 0$, the negative part of c_j (thus at least one of them is always zero), the optimization problem (17) turns into the following

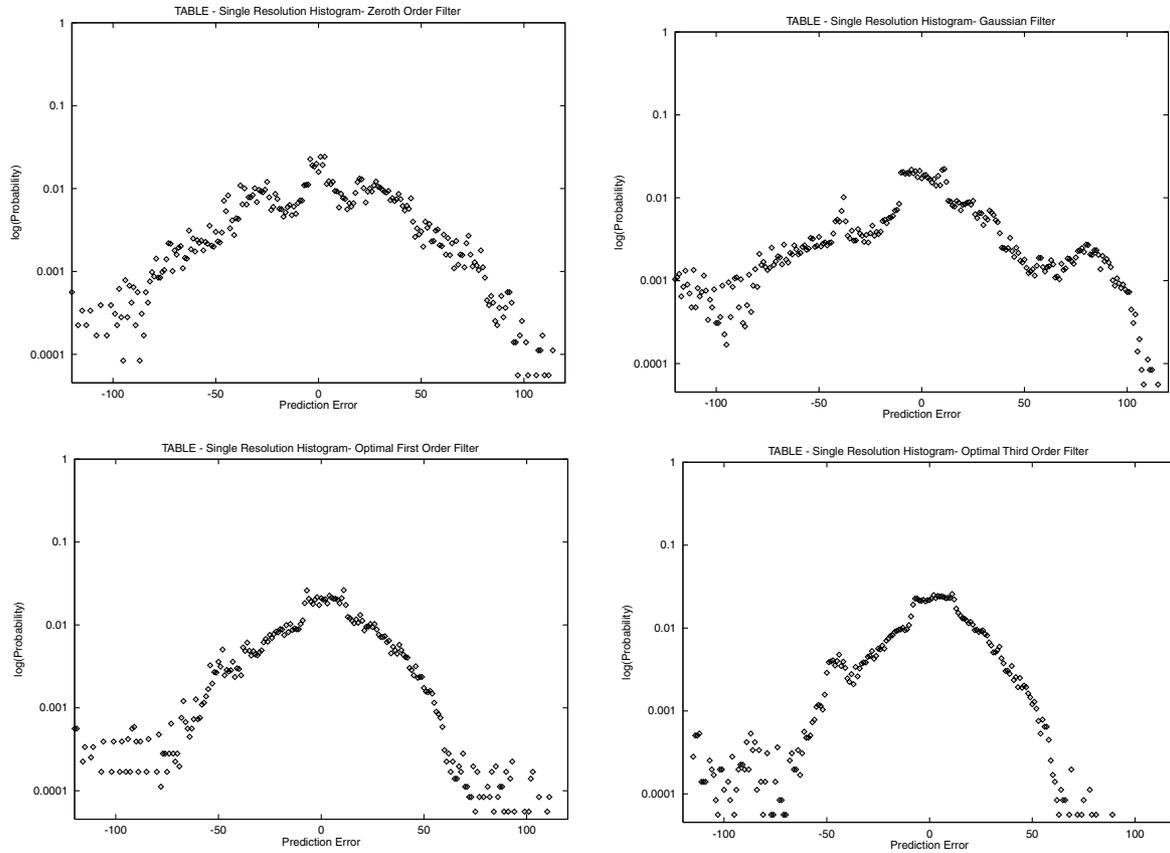

Fig. 7. Semilog histograms of the prediction errors associated to the four filters for the Single Resolution scheme applied to the round table rendered in Fig. 5.

linear programming problem:

$$\begin{aligned} & \max_{w, f_j, g_j, u_i, v_i} \left[-w - \varepsilon \sum_{j=0}^d (f_j + g_j) \right] \\ & \text{subject to : } w, f_j, g_j, u_i, v_i \geq 0 \end{aligned} \tag{18}$$

$$b_i = u_i + \sum_{j=0}^d a_{ij}(f_j - g_j) - w$$

$$b_i = -v_i + \sum_{j=0}^d a_{ij}(f_j - g_j) + w$$

with ε a small number to enforce at least one of f_j or g_j to be zero (for instance $\varepsilon = 10^{-6}$). With the standard simplex algorithm, this problem requires the storage of a $(2nV + 2) \times (2nV + 2d + 2)$ -matrix (the so-called *tableaux*) which is prohibitive for large number of vertices (nV of order 10^5 , for instance). In any case, the moral of this subsection is to point out that the more accurate predictor is the one that achieves a lower l^∞ -norm error.

4.2. Robustness

Consider now the following scenario: the differences associated to the prediction algorithm are not set to zero

but perturbed by some random quantities. This may be due to several causes. We can either imagine irretrievable transmission errors or even a resampling process at the transmitter to reduce the code length of the entire object. In any case, we assume the true difference d_i is perturbed by some stochastic process v_i . Thus, the reconstructed geometry has the form

$$x_i^{l-1;reconstr} = x_i^{l-1;updt} + diff_i + v_i.$$

We assume the perturbations are about of the same size as the prediction differences. Next, suppose we want to minimize *in average* the effect of these perturbations. Then, one such criterion is the noise variance $E[v_i^2]$. Assuming the stochastic process is ergodic, it follows that the noise variance can be estimated by the average of all the coordinate perturbations:

$$E[v_i^2] = \frac{1}{N} \sum_{i=0}^{N-1} v_i^2.$$

Next, since the perturbation is of the same order as the prediction error, the later term can be replaced by the average of the differences. Hence, we want to minimize:

$$E[v_i^2] \approx \frac{1}{N} \sum_{i=0}^{N-1} d_i^2$$

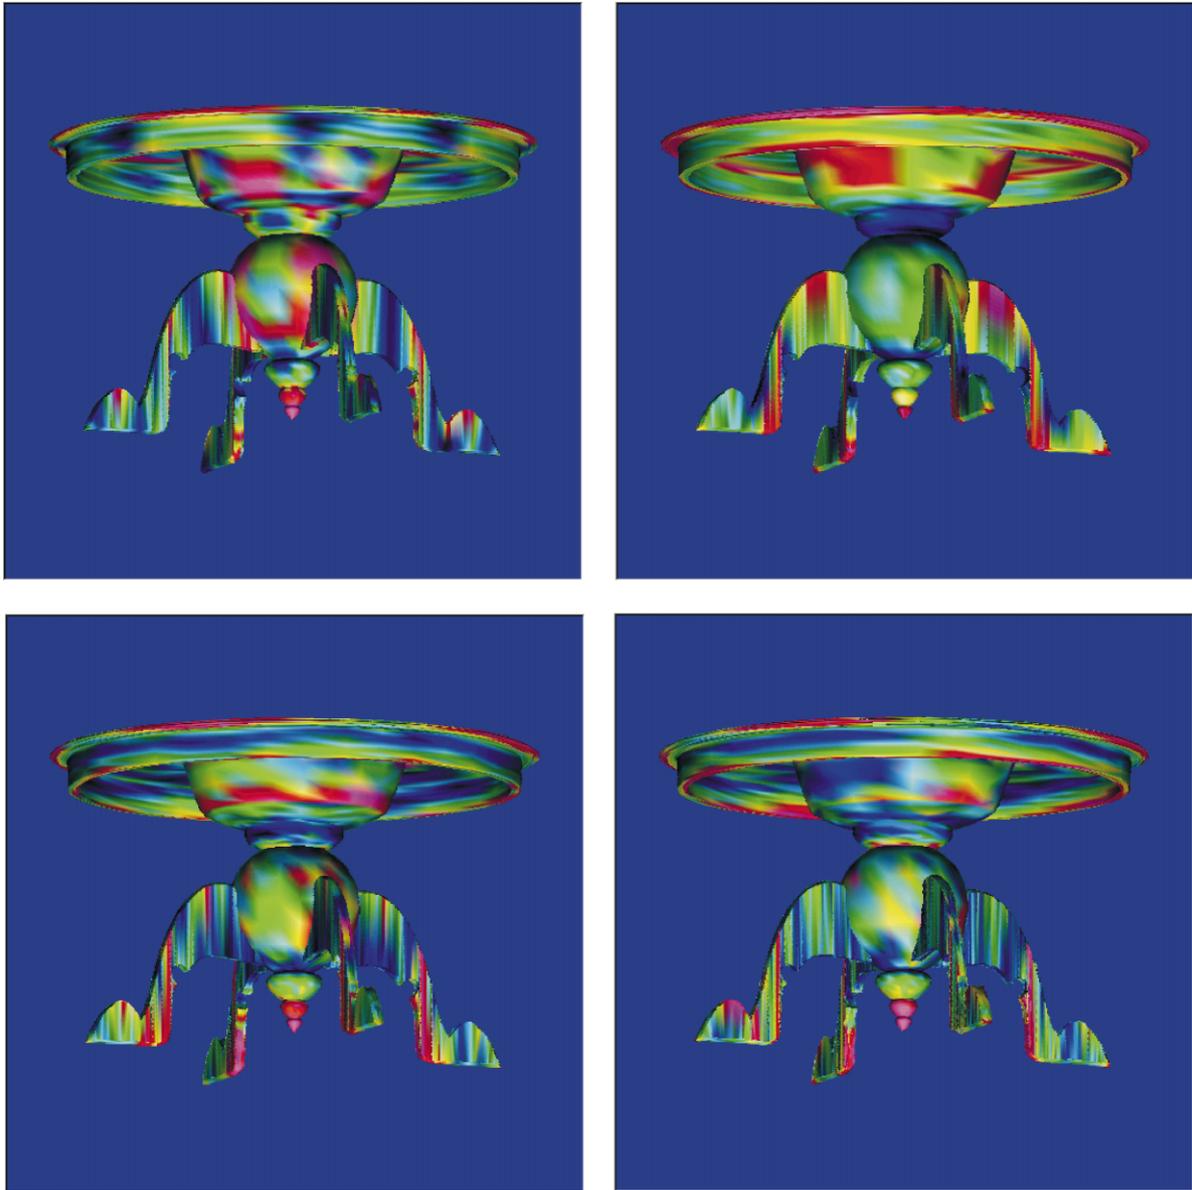

Fig. 8. The color plot of the single resolution approximation errors for the four different filters: Zeroth Order Filter (upper left); Gaussian Smoothing (upper right); LS first order (lower left) and LS third order (lower right).

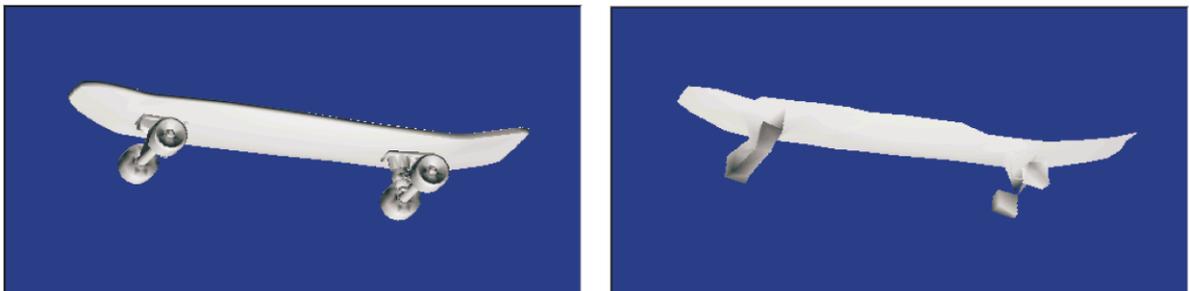

Fig. 9. The skateboard mesh at the finest resolution (left) and the coarsest resolution (right) after eight levels of reduction.

Fig. 10. The skateboard mesh at the finest resolution level when no difference is used and the filtering is performed by: the Zeroth Order Filter (top left); the Gaussian Smoother (top right); the least squares filter of order 1 (bottom left) and the least squares filter of order 3 (bottom right).

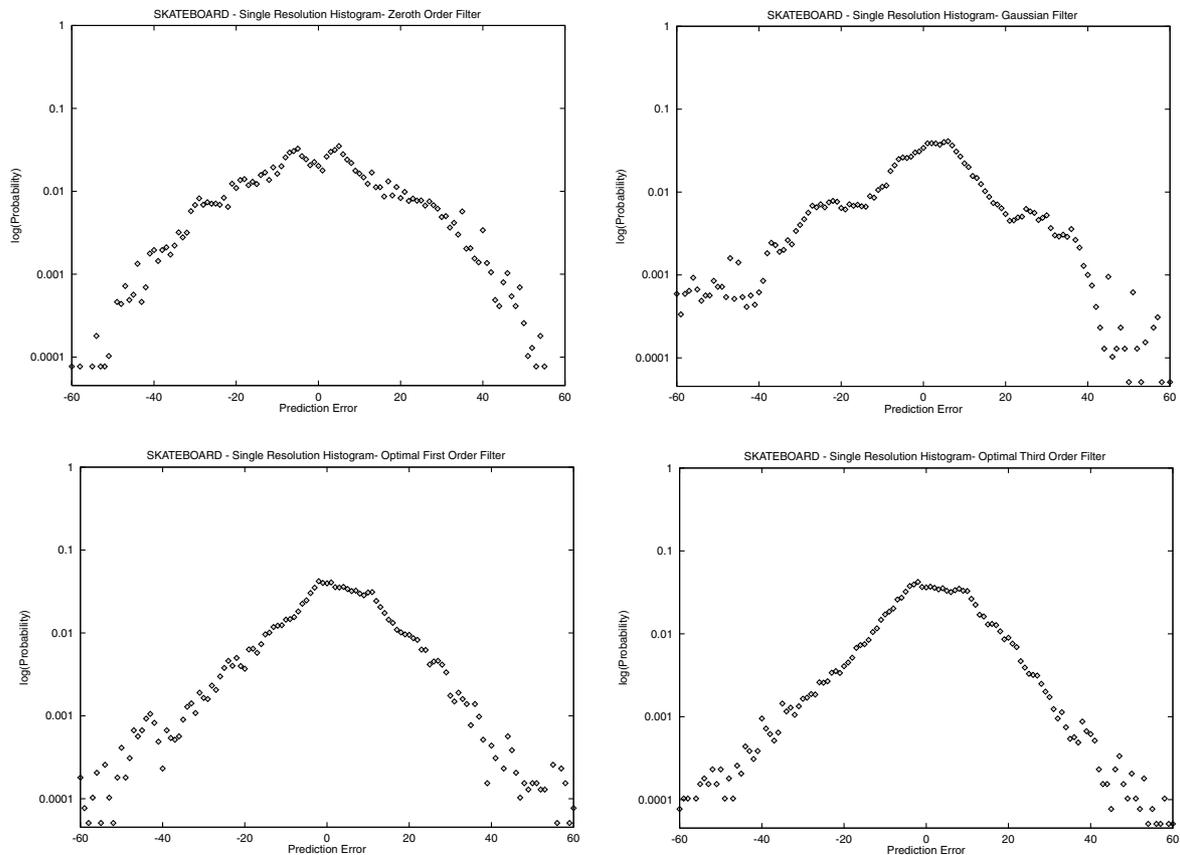

Fig. 11. Semilog histograms of the prediction errors associated to the four filters for the Single Resolution scheme applied to the mesh rendered in Fig. 9.

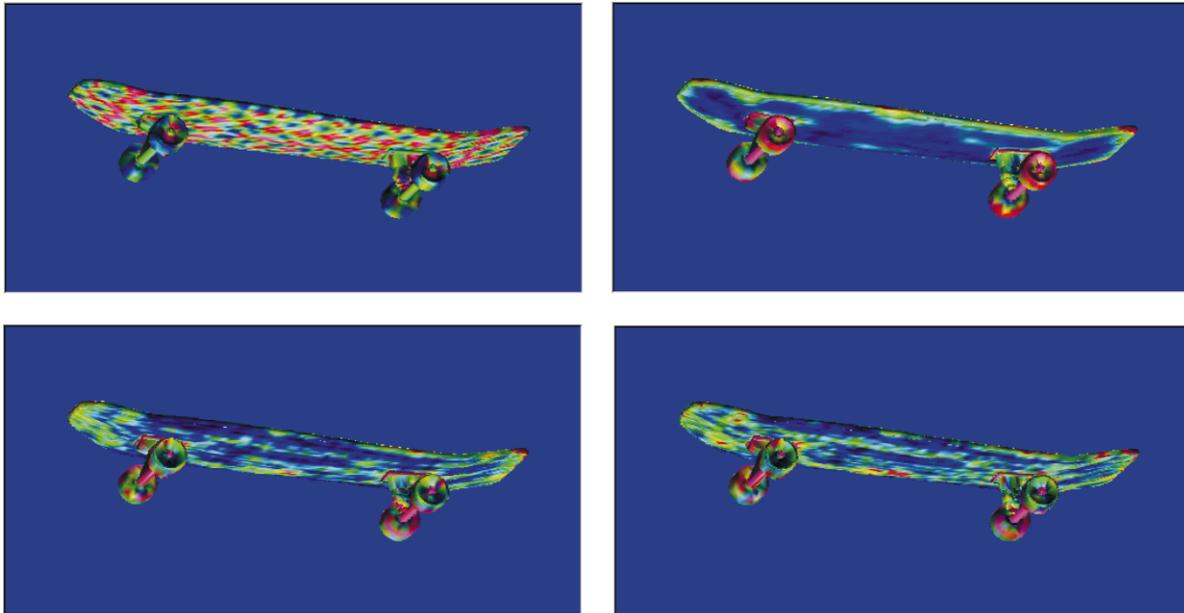

Fig. 12. The color plot of the single resolution approximation errors for the four different filters: Zeroth Order Filter (upper left); Gaussian Smoothing (upper right); LS first order (lower left) and LS third order (lower right).

This shows that a criterion of robustness is the total energy of the differences. In this case, our goal to increase the robustness of the algorithm is achieved by decreasing the l^2 -norm of the prediction errors. Thus, the filters are the solvers of the optimization problem (13) for $p = 2$. The solution in terms of filter coefficients is very easily obtained by using the pseudoinverse matrix. Thus, the solution of:

$$\inf_c \|A_c - b\|_2$$

is given by:

$$c = (A^T A)^{-1} A^T b \tag{19}$$

4.3. Compression ratio

The third property we discuss now is the compression ratio the algorithm achieves. In fact, if no error or further quantization is assumed, the compression ratio is perhaps the most important criterion in judging and selecting an

algorithm. In general, estimating compression ratios is a tough problem due to several reasons. First of all, one should assume a stochastic model of the data to be encoded. In our case, we encode the vectors of prediction errors, which in turn depend on the mesh geometry and the way we choose the filters' coefficients. Next, one should have an exact characterization of the encoder's compression ratio. The best compression ratio, assuming a purely stochastic data, is given by Shannon's entropy formula and, consequently, by the entropy encoder which strives to achieve this bound (Shannon-Fano and Huffman codings—see Ref. [21] or [2]). However, the entropy encoder requires some a priori information about the data to be sent, as well as overhead information that may affect the global compression ratio. Alternatively, one can use adaptive encoders like the adaptive arithmetic encoder as in the JPEG/MPEG standards (see Ref. [13]). This encoder may perform better in practice than blind entropy or arithmetic encoders, however, it has the important shortcoming that its

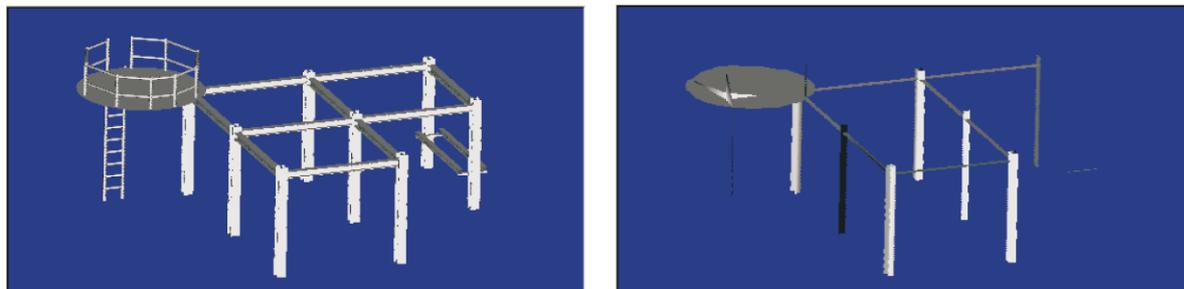

Fig. 13. The piping mesh at the finest resolution (left) and the coarsest resolution (right) after seven levels of reduction.

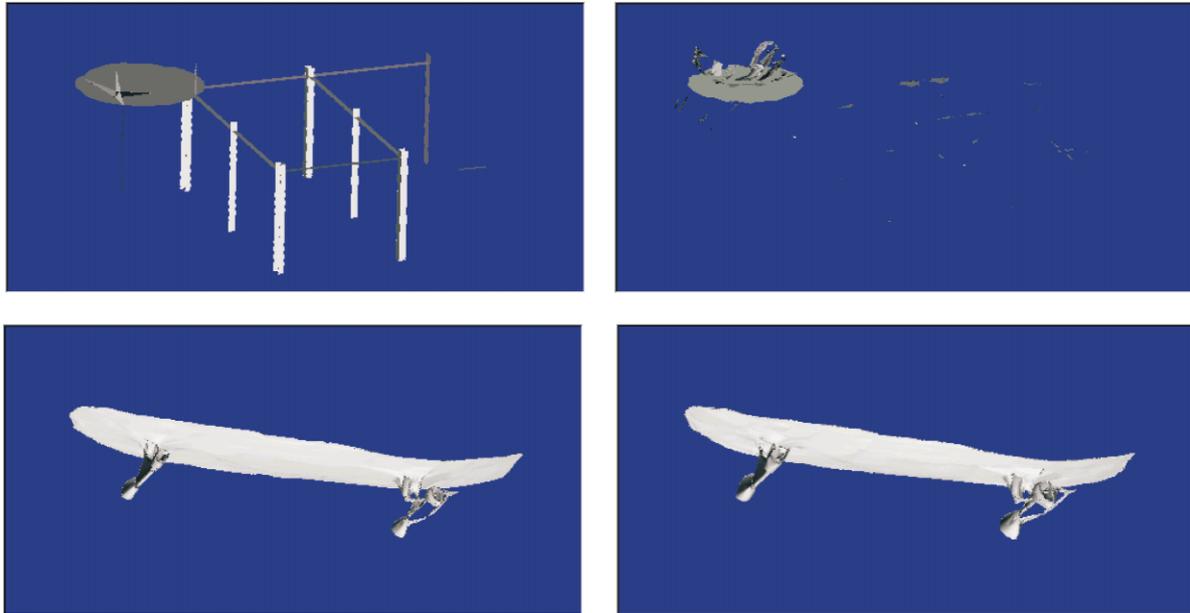

Fig. 14. The piping mesh at the finest resolution level when no difference is used and the filtering is performed by: the Zeroth Order Filter (top left); the Gaussian Smoother (top right); the least squares filter of order 1 (bottom left) and the least squares filter of order 3 (bottom right).

compression ratio is not characterized by a closed formula. In any case, for purely stochastic data the best compression ratio is bounded by Shannon’s formula, which we discuss next. We thus assume our bit sequence encoding scheme achieves this optimal bound. Suppose the quantized differences x_i , $0 \leq i \leq N - 1$, are independently distributed and have a known probability distribution, say $p(n)$, $-2^{B-1} \leq n \leq 2^B$. Thus $p(n)$ is the probability that a difference is n . In this case, the average (i.e. expected value) of the number of bits needed to encode one such difference is not less than:

$$R_{Shannon} = - \sum_{n=-2^{B-1}}^{2^B-1} p(n) \log_2 p(n)$$

where 2^B is the number of quantization levels (see Ref. [19]). Assuming now the ergodic hypothesis holds true, $p(n)$ can be replaced by the repetition frequency $p(n) = f(n)/N$, where $f(n)$ is the repetition number of the value n and N the total number of values (presumably $N = 3nV$). Thus, if we replace the first $p(n)$ in the above formula by this

frequency, the sum turns into

$$R = - \frac{1}{N} \sum_{i=0}^{N-1} \log_2 p(n = x_i)$$

Note the summation index has changed. At this point we have to assume a stochastic model for the prediction errors. We consider the power-type distribution that generalizes both the Gaussian and Laplace distributions, that are frequently used in computer graphics models (see Ref. [12], for instance):

$$p(x) = \frac{a^{\frac{1}{\alpha}} \alpha}{2\Gamma\left(\frac{1}{\alpha}\right)} \exp(-a|x|^\alpha) \tag{20}$$

where $\Gamma(x)$ is the Euler’s Gamma function (to normalize the expression) and a is a parameter. For $\alpha = 1$ it becomes the Laplace distribution, whereas for $\alpha = 2$ it turns into the Gauss distribution. Then, the previous rate formula

Filter's degree	1	2	3	4	5	6	7
bits/vertex	14.37	14.32	14.36	14.45	14.48	14.54	16.01

turns into:

$$R = R_0 + \frac{a \log_2 e}{N} \sum_{i=0}^{N-1} |x_i|^\alpha,$$

$$R_0 = 1 + \log_2 \Gamma\left(\frac{1}{\alpha}\right) - \log_2 \alpha - \frac{1}{\alpha} \log_2 a$$

Now we replace the parameter a by an estimate of it. An easy computation shows the expected value of $|x|^\alpha$ for the α -power p.d.f. (Eq. (20)) is $E[|x|^\alpha] = 1/\alpha a$. Thus, we get the

following estimator for the parameter a :

$$\hat{a} = \frac{1}{\alpha} \frac{N}{\sum_{i=0}^{N-1} |x_i|^\alpha}$$

and the above formula of the rate becomes:

$$R = \rho_0(\alpha) + \frac{1}{\alpha} \log_2 \left[\sum_{i=0}^{N-1} |x_i|^\alpha \right], \tag{21}$$

$$\rho_0(\alpha) = 1 + \log_2 \frac{\Gamma\left(\frac{1}{\alpha}\right)}{\alpha} + \frac{1}{\alpha} \log_2 \frac{e\alpha}{N}$$

Consider now two linear predictors associated to two different linear filters. Each of them will have different prediction errors. If we assume the prediction errors are independent in each case and distributed by the same power law with exponent α but maybe different parameters a_1 , respectively a_2 , then the prediction scheme that yields

the sequence of differences with smaller l^α -norm has a better (entropic) compression bound and, therefore, is more likely to achieve a better compression ratio. Equivalently, the p.d.f. that has a larger parameter a , or is narrower, would be encoded using fewer bits.

The argument we presented here suggests that a better compression ratio is achieved by the prediction scheme that minimizes the l^α -norm of the prediction error, where α is the p.d.f.'s characteristic exponent (when it is a power-type law), usually between 1 (the Laplace case) and 2 (the Gaussian case). For $p = 2$, the optimizing filter is found by using the pseudoinverse of A as in Eq. (19). For $p = 1$, the optimizer solves the linear programming problem:

$$\max_{f_j, g_j, u_i, v_i} \sum_{i=0}^{N-1} \left[-u_i - v_i - \varepsilon \sum_{j=0}^d (f_j + g_j) \right]$$

subject to : $f_j, g_j, u_i, v_i \geq 0$ (22)

$$b_i = u_i - v_i + \sum_{j=0}^d a_{ij}(f_j - g_j)$$

with ε as in Eq. (18), which involves (in the simplex algorithm) a $(N + 2) \times (2N + 2d + 1)$ matrix and the same computational problems as Eq. (18).

5. Examples

In this section, we present a number of examples of our filtering algorithm. For several meshes, we study the accuracy the fine resolution mesh is approximated, and also the compression ratio obtained for different filter lengths.

First, we analyze the basic encoding algorithm presented in Section 3. The filters' coefficients are obtained by solving the optimal problem (13) for $p = 2$, i.e. we use the least-squares solution.

The car mesh represented in Fig. 1 (left) having $nV_0 = 12,784$ vertices and 24,863 faces is decomposed into a sequence of eight levels of detail. The coarsest resolution mesh of $nV_7 = 219$ vertices is rendered in Fig. 1 (right). We used several filter lengths to compress the meshes. In particular, we study four types of filters, namely the Zeroth Order Filter, the Gaussian Smoother and filters of order $d = 1$ and $d = 3$ (decomposed in power basis). The last two filters will be termed as "higher order filters", although their order is relatively low. To check the accuracy of the approximation, we used the prediction algorithm assuming the differences are zero at all levels. The four meshes corresponding to the four filters are represented in Fig. 2.

Note the Zeroth Order Filter does not change the geometry at all (because of its pure extension nature). It gives the worst approximation of the mesh, yet it has the best

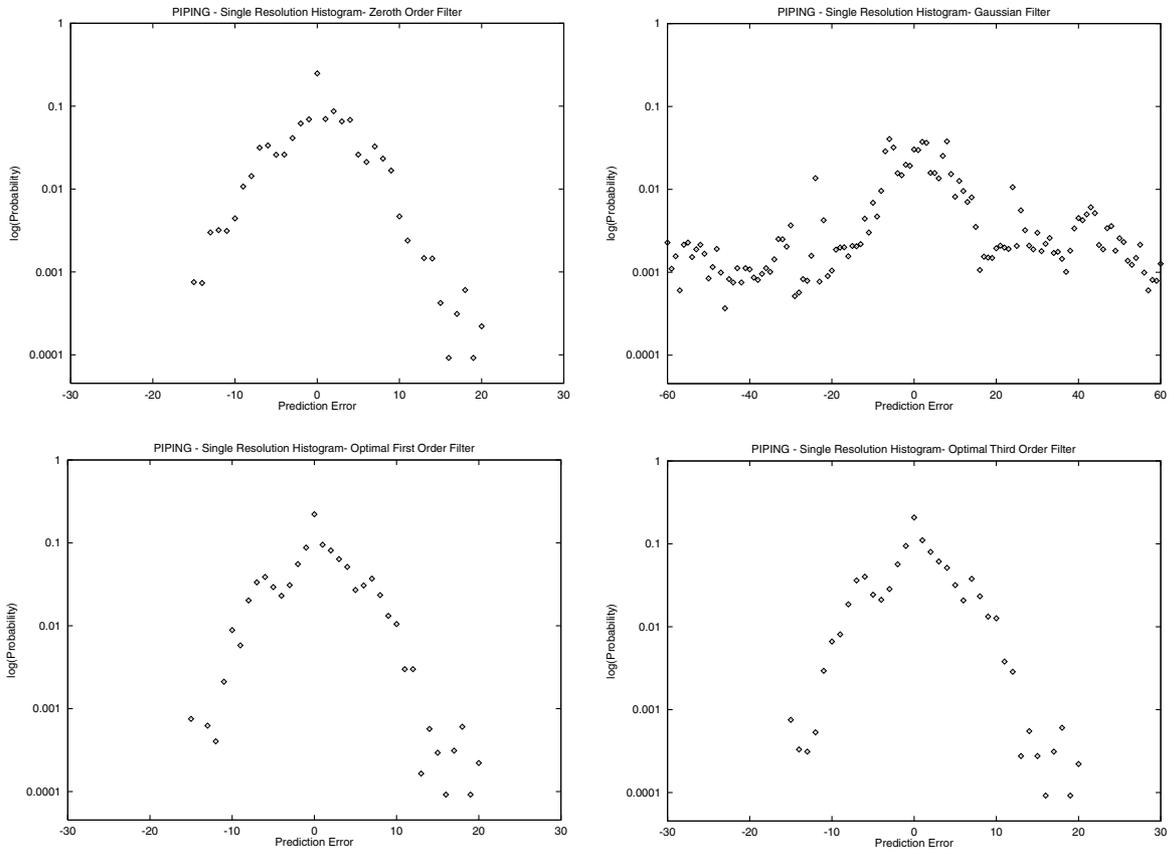

Fig. 15. Semilog histograms of the prediction errors associated to the four filters for the Single Resolution scheme applied to the mesh rendered in Fig. 13.

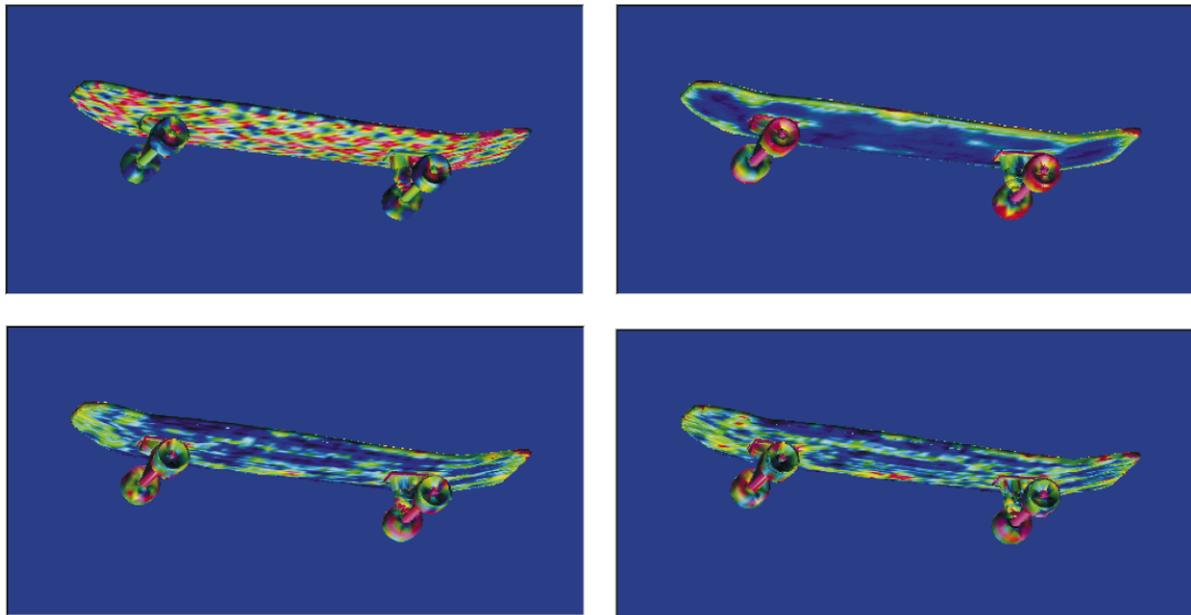

Fig. 16. The color plot of the single resolution approximation errors for the four different filters: Zeroth Order Filter (upper left); Gaussian Smoothing (upper right); LS first order (lower left) and LS third order (lower right).

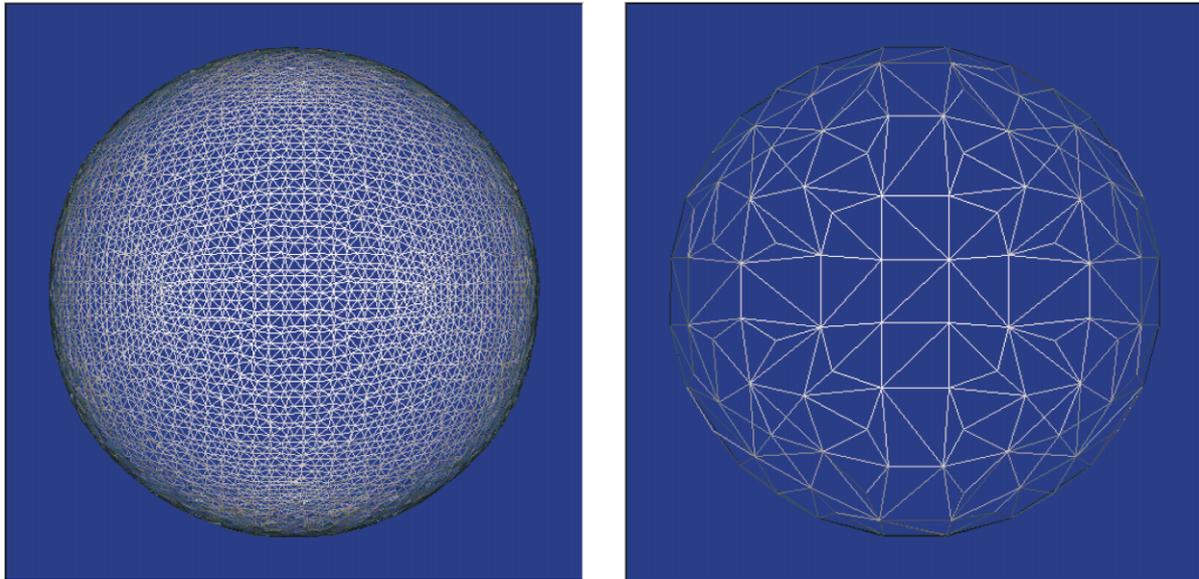

Fig. 17. The sphere at the finest resolution (left) and the coarsest resolution (right) after four levels of reduction.

compression ratio (see below). The Gaussian filter smooths out all the edges, a natural consequence since it really corresponds to a discrete diffusion process. The higher order filters (i.e. first order and third order) trade-off between smoothing and compression.

In terms of the compression ratio, the four filters have performed as shown in Table 3. Varying the filter length, we found the compression ratios indicated in Table 4: all the results apply to the geometry component only. The connectivity is not presented here.

Next we study the variable length encoding algorithm for the four particular filters mentioned before with the parameter $S = nL$ (i.e. in the Single Resolution case). Thus, the mesh geometry is obtained by successively filtering the extensions of the coarser mesh and, at the last level, the true differences are encoded. In terms of accuracy, we obtained very similar meshes. More significantly are the compression ratios, shown in Table 5. To analyze the compression ratios of these four filters, we also have plotted the histogram of the errors on a semilogarithmic scale in Fig. 3. Note the power-type p.d.f. hypothesis is well satisfied by the Zeroth, LS 1st and LS 3rd order filters, and less by the Gaussian smoother. Also as smaller the l^2 -norm error gets, as narrower the p.d.f. and as smaller the rate becomes, in accordance with the conclusions of Section 4.3.

Equally important is how these errors are distributed on the mesh. In Fig. 4, we convert the actual differences into a scale of colors and set this color as an attribute for each vertex. Darker colors (blue, green) represent a smaller error, whereas lighter colors (yellow, red) represent a larger prediction error. The darker the color the better the prediction and also the accuracy. All the errors are normalized with respect to the average l^2 -norm error per vertex for

that particular filter. The average l^2 -norm error is given on the last row in Table 5.

Note in the Single Resolution case there is not much difference among the filtering schemes considered. In particular, the higher order filters perform better than the Zeroth Order Filter, and the Gaussian filter behaves similarly to the other filters. This is different to the Multi-Resolution case in Table 3. There, the Gaussian filter behaves very poorly, and the Zeroth Order Filter gives the best compression ratio. In fact it is better than the Single Resolution case (Tables 6 and 7). On the other hand, with respect to the accuracy, the higher order filters give a more accurate approximation than the Zeroth Order Filter.

About the same conclusions hold for three other meshes we used: the round table, the skateboard and the piping construction. The round table rendered in Fig. 5, left, has $nV_0 = 11,868$ vertices and 20,594 faces. The coarsest resolution mesh (at level eight, pictured on the right side) has $nV_7 = 112$ vertices. The predicted mesh after eight levels of decomposition when no difference is used, is rendered in Figs. 6–8.

The skateboard mesh at the finest resolution (left, in Fig. 9) has $nV_0 = 12,947$ vertices and 16,290 faces. At the coarsest resolution (right, in the same figure) it has $nV_7 = 125$ vertices (see also Fig. 10).

The piping construction has $nV_0 = 18,138$ vertices, and after seven levels of details, it is reduced to $nV_0 = 147$ vertices. The first simplification step achieves almost the theoretical bound: from 18,138 vertices, the mesh is simplified to 2520 vertices (Figs. 11 and 12). The original mesh and its approximations are rendered in Figs. 13 and 14.

The last mesh we discuss is somewhat different to the

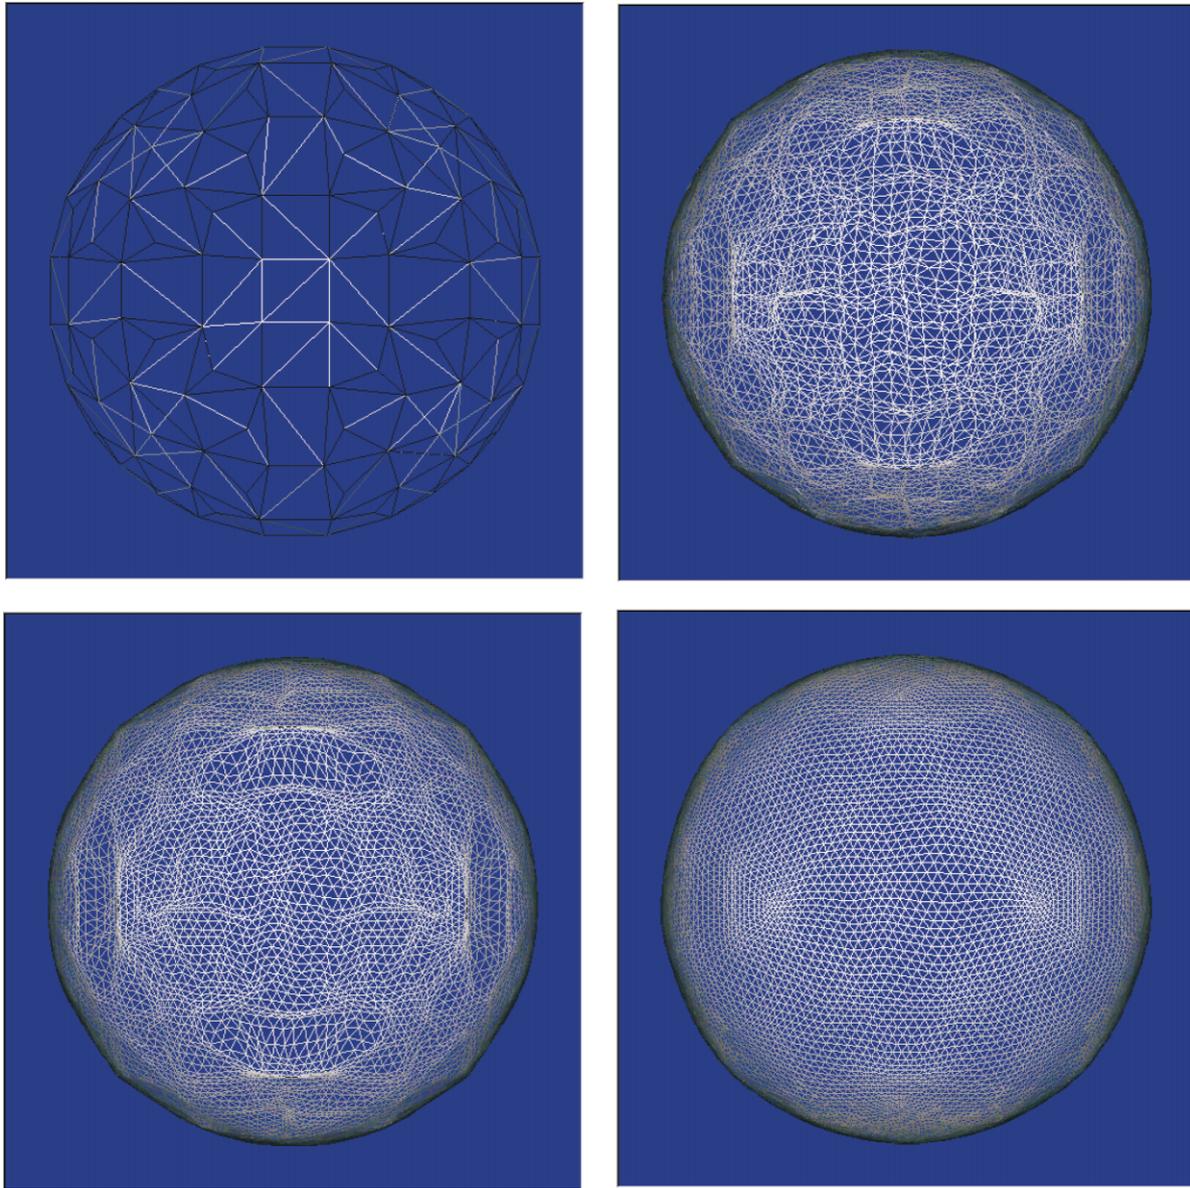

Fig. 18. The sphere at the finest resolution level when no difference is used and the filtering is performed by: the Zeroth Order Filter (top left); the Gaussian Smoother (top right); the least squares filter of order 1 (bottom left) and the least squares filter of order 3 (bottom right).

other. It is a sphere of $nV_0 = 10,242$ vertices and 20,480 faces that reduces after four levels to $nV_3 = 224$ vertices. The striking difference is the compression ratio of the Zeroth Order filter: it is the worst of all the filters we checked (Tables 8–16). Even the Gaussian filter fares better than this filter (Figs. 15 and 16). Snapshots of the approximated meshes are pictured in Figs. 17 and 18. The mesh used is non-manifold but this is not a problem for the geometry encoder. The histograms shown in Fig. 19 are in accordance with the rate results presented in Table 17: the narrower the distribution the better the rate. Note also how well a power-type low fits the 3rd order filtered distribution (Fig. 20).

These examples show that in terms of compression ratio,

the Zeroth Order Filter compresses best the irregular and less smooth meshes, whereas higher order filter are better for smoother and more regular meshes. However, in terms of accuracy and robustness, the higher order filters perform much better than its main “competitor”, the Zeroth Order Filter. Note, except for highly regular meshes (like sphere, for instance), relatively low-order filters are optimal. The range [1...5] seems enough for most of the encoding schemes.

6. Conclusions

In this paper, we study the 3D geometry filtering using the

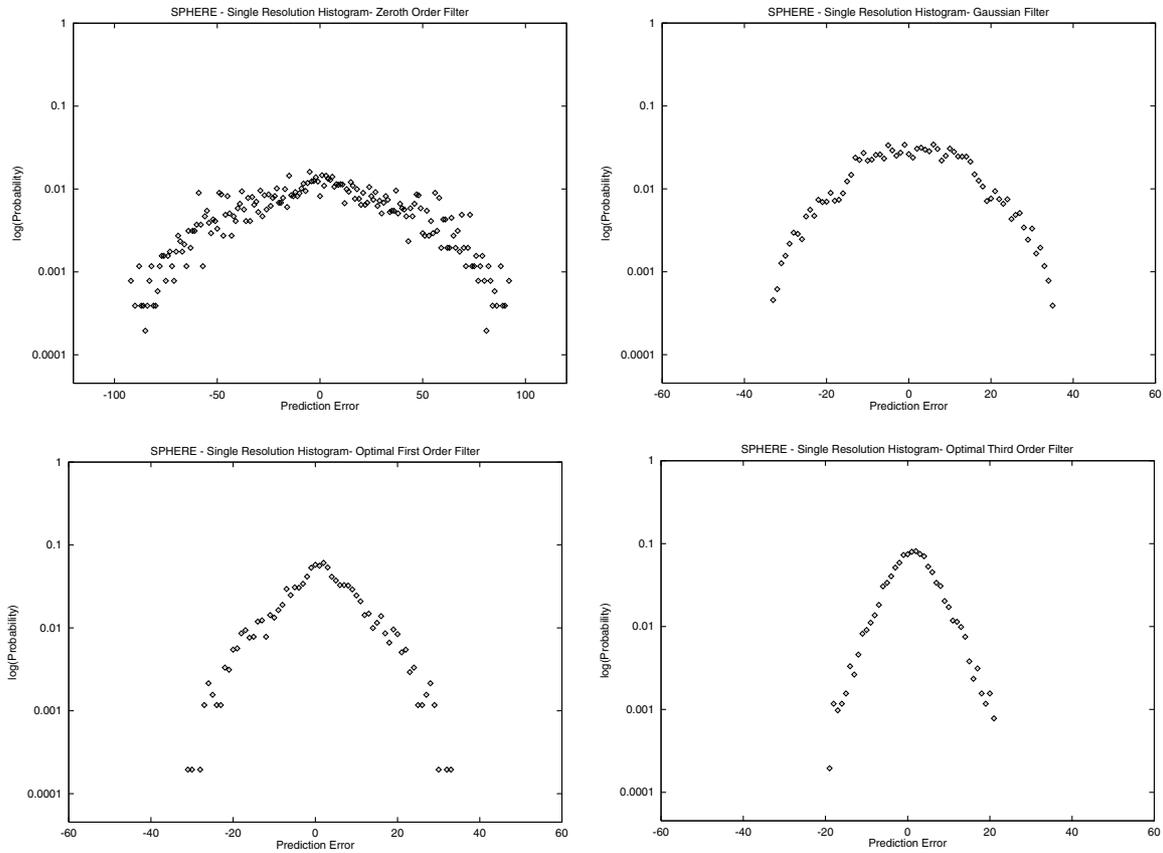

Fig. 19. Semilog histograms of the prediction errors associated to the four filters for the Single Resolution scheme applied to the sphere mesh rendered in Fig. 17.

discrete Laplace operator. We next apply the filtering technique to Multi Resolution Analysis where the original mesh is converted into a sequence of successive refinements. Based on the coarser resolution mesh, the finer resolution mesh is predicted using an extension map followed by filtering. At each level, the coordinate vectors are filtered separately using different filters. These filters are optimizers of some prediction error norm. Thus the geometry of a sequence of successively refined meshes is encoded in the following format: first the coarsest resolution mesh geometry and next for each successive level, the filters coefficients

and prediction errors. The connectivity information is supposed to be known at each level separately.

Next, we study several desirable properties of any encoding scheme, finding for each one the appropriate criterion to be optimized. Thus, for a better accuracy of the predicted mesh when no difference is available, the filter coefficients should minimize the l^∞ -norm of the prediction errors. For robustness, as understood in signal processing theory, the filters should minimize the l^2 -norm of the differences. The third property, the compression rate, is maximized when the l^∞ -norm is replaced by a l^α -norm with α usually

Table 17

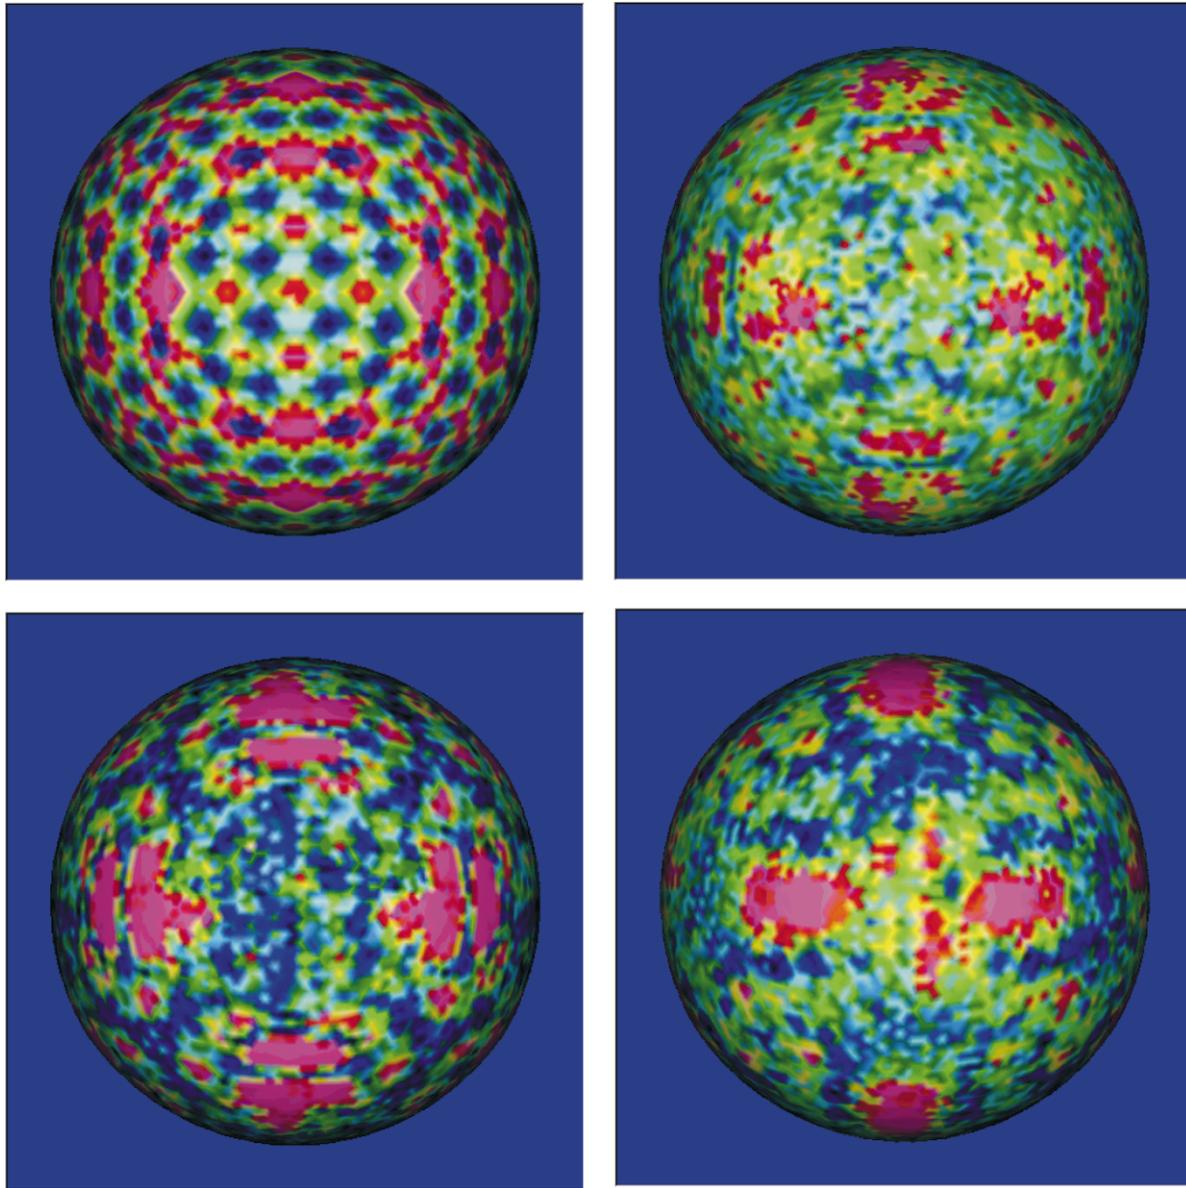

Fig. 20. The color plot of the single resolution approximation errors for the four different filters: Zeroth Order Filter (upper left); Gaussian Smoothing (upper right); LS first order (lower left) and LS third order (lower right).

between 1 and 2, depending on the prediction error's p.d.f. Thus, if the differences are Laplace distributed, the l^1 -norm should be minimized, whereas if they are Gaussian, then the l^2 -norm should be used. In any case, each of the three extreme cases (l^∞ , l^2 or l^1) can be solved exactly. The l^2 -norm case is the simplest and relatively computational inexpensive, and is solved by a linear system. The other two cases turn into linear programming problems, which are computationally expensive to solve.

These theoretical results are next applied to concrete examples. In general for large, non-smooth and irregular meshes the Zeroth Order Filtering scheme yields the best compression ratio, but the poorest accuracy or, for the same reason, robustness. Instead, by paying a

small price in the compression ratio, a least-square filter gives a better rendering accuracy and superior robustness. At the other end of the scale, for very smooth and regular meshes, the Gaussian filter (which in general behaves very poorly) gives a better compression ratio than the Zeroth Order filter.

The basic encoding algorithm can be modified to allow a variable structure. The user can choose for what levels the differences are encoded and, by choosing a limit case, only the highest resolution level errors are encoded. Thus, the MRA scheme becomes a Single Resolution encoding scheme. Examples in terms of accuracy and compression ratio are shown in Section 5.

The novelty of this study consists in using linear filter in

Multi-Resolution encoding schemes and finding appropriate optimization criteria for specific compression or rendering properties. We hope this compression scheme will prove effective in Progressive Transmission protocols as MPEG4.
